Impact of a simulation-based training on the experience of the beginning of residency

Bénédice d’une séance de simulation médicale sur le vécu du début d’internat en médecine interne

Abstract

Introduction. – We aimed to evaluate the impact of an immersive simulation session on the experience of the beginning of residency.

Methods. – The intervention group consisted of newly recruited residents in 2019, who participated in the workshop presenting four emergency scenarios frequently encountered during night shifts; the control group comprised residents who had begun their internship in 2018, without having participated in the simulation workshop. The level of psychological stress and self-confidence were self-estimated in the simulation group before and immediately after the workshop. During the second semester of residency, stress, self-efficacy and anxiety were evaluated in both groups with the Perceived Stress Scale (PSS), General Self-efficacy Scale (GSES), and Generalized Anxiety Disorder-7 (GAD-7) scale.

Results. – In the second semester 2020, the PSS, GSES and GAD-7 were 20.71 ± 8.15 and 22.44 ± 5.68 (P = 0.40); 26.88 ± 6.30 and 27.11 ± 3.95 (P = 0.87); 6.94 ± 5.25 and 8.89 ± 4.78 (P = 0.22) for the simulation (n = 17, 89.5% of participation) and control (n = 9, 75%) groups, respectively. In the simulation group, the level of self-confidence had significantly improved from 1.82 ± 0.95 before the session to 2.29 ± 1.16 after the session (P < 0.05). Interestingly, this improvement in self-confidence was significantly correlated with GAD-7 (P = 0.014) and PSS (P = 0.05), and tended to be correlated with GSES (P = 0.09).

Conclusion. – Our study showed a significant improvement in self-confidence between before and after the simulation session. Residents who experienced an improvement in self-confidence saw their stress and anxiety levels decrease during the second semester reevaluation, in favor of a prolonged benefit from the session.
